Abstract

Laboratory measurements of physiological and demographic tolerances are important in understanding the impact of climate change on species diversity; however, it has been recognized that forecasts based solely on these laboratory estimates overestimate risk by omitting the capacity for species to utilize microclimatic variation via behavioral adjustments in activity patterns or habitat choice. The complex, and often context-dependent nature, of microclimate utilization has been an impediment to the advancement of general predictive models. Here, we overcome this impediment and estimate the potential impact of warming on the fitness of ectotherms using a benefit/cost trade-off derived from the simple and broadly documented thermal performance curve and a generalized cost function. Our framework reveals that, for certain environments, the cost of behavioral thermoregulation can be reduced as warming occurs, enabling behavioral buffering (e.g., the capacity for behavior to ameliorate detrimental impacts) and “behavioral rescue” from extinction in extreme cases. By applying our framework to operative temperature and physiological data collected at an extremely fine spatial scale in an African lizard, we show that new behavioral opportunities may emerge. Finally, we explore large-scale geographic differences in the impact of behavior on climate-impact projections using a global dataset of 38 insect species. These multiple lines of inference indicate that understanding the existing relationship between thermal characteristics (e.g., spatial configuration, spatial heterogeneity, and modal temperature) is essential for improving estimates of extinction risk.

KEYWORDS

behavioral thermoregulation, climate change, ecological forecasting, environmental variation, macrophysiology, temperature

1 | INTRODUCTION

A critical challenge in current ecological research is to understand how environmental temperature regimes limit the abundance and distribution of species with sufficient accuracy to enable predictions of the future effects of climate change (Kearney, Shine, & Porter, 2009; Porter & Kearney, 2009; Williams, Shoo, Isaac, Hoffmann, & Langham, 2008). Recent advances have emphasized organismal traits, such as the thermal dependence of population growth rate, as the mechanistic basis for understanding how changing environmental conditions may determine the vulnerability of populations (particularly ectotherm populations) to extinction (Dell, Pawar, & Savage, 2013; Kearney & Porter, 2009; Kearney et al., 2009; Litchman & Klausmeier, 2008; Sinervo et al., 2010). However, while thermal performance traits are usually assessed in controlled laboratory conditions, performance in nature is mediated by the ability of ectothermic organisms to manage their body temperature behaviorally (Buckley, Ehrenberger, & Angilletta, 2015; Long et al., 2014; Porter & Gates, 1969). In addition to the physiological mechanisms used to heat and cool their bodies (Holland, Brill, Chang, Sibert, & Fournier, 1992), ectotherms regulate their body temperature through microhabitat choice (Huey, 1974; Logan, Huynh, Precious, & Calsbeek, 2013; Porter, Mitchell, Beckman, & DeWitt, 1973; Scheffers, Edwards, Diesmos, Williams, & Evans, 2014; Scheffers, Evans, Williams, & Edwards, 2014; Woods, Dillon, & Pincebourde, 2015), thereby expending energy to seek out areas within their habitat that are thermally favorable (e.g., behaviorally thermoregulating; Kearney et al., 2009; Sears et al., 2016; Sunday et al., 2016). The decision to thermoregulate or thermoconform has been shown to depend on the cost of thermoregulation (Huey, 1974; Huey & Slatkin, 1976); these costs are strongly dependent on the spatial structure of the thermal environment (Huang, Porter, Ming-Chung, & Chiou, 2014; Pincebourde, Murdock, Vickers, & Sears, 2016; Sears et al., 2016) and have been refined by recent advances in the resolution of spatial data at the small and microscales important for many ectotherms (Logan et al., 2013; Scheffers, Edwards, et al., 2014; Scheffers, Evans, et al., 2014; Woods et al., 2015). Therefore, accurate ecological forecasts amidst climate warming necessitate a tractable approach for harmonizing how these categories of environmental and organismal data inform each other.

Despite decades of research highlighting the importance of behavior to mediate fitness, animal behavior has been excluded from many recent broad-scale climate-impact projections (Deutsch et al., 2008; Thomas, Kremer, Klausmeier, & Litchman, 2012; Vasseur et al., 2014), which generates several potential sources of potential bias. First, assuming movement behavior is adaptive (i.e., that it increases physiological performance) forecasts ignoring behavior will generally overemphasize the detrimental impacts of warming (Pincebourde et al., 2016), particularly when the net benefits of behavioral thermoregulation remain high during periods of elevated environmental temperatures (Sears, Raskin, & Angilletta, 2011). Indeed, the ability

of organisms to behaviorally thermoregulate currently enables the persistence of populations in environments that would otherwise exceed physiological limits (Sunday et al., 2016), and is predicted to be a key ecological feature enabling the persistence of populations in response to sustained climate warming (Huey et al., 2012; Kearney et al., 2009; Sears et al., 2016). Yet, the anticipated net benefits of thermoregulatory behaviors will vary dramatically across organisms and ecosystems—ranging from situations where environmental warming may provide new opportunities for behavior to increase fitness above current levels (Huey, Hertz, & Sinervo, 2003; Logan et al., 2013) to instances where, despite movement abilities and the capacity for behavioral thermoregulation, climate warming will likely restrict the ability of organisms to survive and reproduce (Caillon, Suppo, Jérôme Casas, Woods, & Pincebourde, 2014; Sinervo et al., 2010). As such, understanding how to modify macroecological patterns of climate-impact projections to include behavior is of high priority.

The factors influencing decisions surrounding behavioral thermoregulation are myriad (Basson, Levy, Angilletta, & Clusella-Trullas, 2017; Porter et al., 1973; Sears et al., 2016), but the winning thermoregulatory strategy ultimately depends on the relative costs and benefits associated with movement behavior (Huey, 1974; Huey & Slatkin, 1976). While much research has focused on how features of organisms (e.g., body size, velocity, reliance on evaporative cooling; Huey et al., 2012; Huey & Slatkin, 1976; Kearney et al., 2009; Porter & Kearney, 2009; Shine & Kearney, 2001; Sunday et al., 2016) or properties of the environment (e.g., the available and configuration of preferred thermal habitat, or the modal environmental temperature) impact the costs of behavioral thermoregulation and ultimately fitness (Huey & Slatkin, 1976; Logan, Fernandez, & Calsbeek, 2015; Logan et al., 2013; Martin & Huey, 2008; Sears et al., 2016, 2011), little emphasis has been placed on understanding how the existing relationship between thermal characteristics may influence the costs associated with behavioral thermoregulation. Yet, these relationships (e.g., the existence of a correlation between spatial heterogeneity and mean temperature) define the conditions over which costs and benefits of thermoregulation will be realized during environmental extremes and ultimately shape the constraints and opportunities for behavior to rescue populations from being locally extirpated amidst changing climatic conditions.

Here, we identify that, and explore how, existing relationships between thermal characteristics can constrain or enable opportunities for behavioral thermoregulation amidst warming. We begin by presenting a general framework that incorporates thermal physiology and spatio-temporal variability in environmental temperature to predict thermoregulatory behavior and ultimately the performance of ectotherms in nature. Our approach is not intended to displace the important and necessary work on the physics and physiology of behavioral thermoregulation (e.g., Kearney & Porter, 2009; Shine & Kearney, 2001), rather to describe the environmental conditions that are most ripe for behavior to play an important role under climate change and to expand our ability to update the extinction budget for larger classes of organisms. We use this approach to explore how relationships between the

spatial mean temperature and the costs of behavioral thermoregulation can influence estimates of fitness. Next, using highly resolved environmental and physiological data from an African lizard, we highlight how warming may provide new opportunities for thermoregulation by altering its underlying cost. Finally, we explore large-scale geographic differences in the predicted impact of behavior on climate-impact projections using a global dataset of 38 insect species and a set of hypotheses about the change in spatial microclimate variation with climate change. Collectively our results indicate that the relationship between the mean temperature, the costs of behavioral thermoregulation, and the structure of microclimatic variation, should be a focal consideration in ongoing climate change research.

2 | THEORETICAL FRAMEWORK

Our framework predicts field performance, which we define as the time-average realized value of the aggregate of vital physiological processes affecting an individual in a spatiotemporally variable

environment. We use the term “field performance” instead of “fitness” because most measures of performance (e.g., survival, swimming speed, eggs produced) do not wholly define the absolute fitness of an individual (Angilletta, 2009; Logan et al., 2013). Field performance can be measured over many individuals in a population to develop a metric of mean population fitness. We develop a cost-benefit model that identifies the body temperature for an individual organism that maximizes performance given its thermal physiology, the current state of the thermal environment, and the costs associated with locomotion to a different microclimate within the broader environment. Here, the thermal environment is represented by a multidimensional, spatially explicit thermal landscape, \mathbb{T} , that is divided into regular discrete microhabitats on a scale that is biologically relevant to the individual organism and characterized by known probability density and autocorrelation functions (Figure 1a). In the absence of behavioral thermoregulation, we assume that an individual is situated at the modal value in this landscape and that its body temperature (T_b) mimics that of its current microhabitat, such that $T_b = \bar{\mathbb{T}}$, which is true so long as the distribution of temperatures across the landscape is unimodal without skewness. The

FIGURE 1 A framework for estimating the performance consequences of behavioral thermoregulation in warming environments. (a) A thermal environment, blue \mathbb{T}_c , represents cool conditions (top left). Warmed environments (red \mathbb{T}_w) have increased mean temperatures, $\bar{\mathbb{T}}$, and relative to cool conditions, are otherwise identical (top right), have increased spatial heterogeneity (bottom left), or have increased spatial autocorrelation (bottom right). (b, c) How warming impacts future performance depends on the magnitude of increase of $\bar{\mathbb{T}}$ and the cost of behavioral thermoregulation within \mathbb{T}_w . The thermal performance curve (thick black curve) defines the relationship between body temperature, T_b , and performance, P . For an environment with mean temperature $\bar{\mathbb{T}}$, the benefit, B , from altering body temperature from $T_b = \bar{\mathbb{T}}$ is defined by ΔP relative to $P(T_b = \bar{\mathbb{T}})$. The cost of altering body temperature is defined by a cost function C : blue curve in (b) represents the cost function for the cool environment and red curve in (c) represents the cost function for a hypothetical warmed environment that has reduced costs of behavioral thermoregulation. The predicted P and T_b for a given \mathbb{T} is calculated as the temperature that maximizes P given B and C

performance of this individual across different body temperatures is given by the thermal performance curve, $P(T_b)$ (Figure 1b,c, thick black curve). This curve is commonly measured under constant laboratory conditions and has well-studied properties (Angilletta, 2006; Deutsch et al., 2008; Thomas et al., 2012). Various mathematical relationships have been proposed to describe $P(T_b)$ (Angilletta, 2006; Deutsch et al., 2008; Sears & Angilletta, 2015; Thomas et al., 2017); here, we use the unimodal function $P(T) = b_1 \exp(b_2 T) - (d_0 + d_1 \exp(d_2 T))$, where the first and second terms of this function correspond to the effect of temperature on birth and death rates, respectively (Thomas et al., 2017).

The benefit (measured in the currency of field performance) of altering body temperature from the initial condition, \bar{T} , is given by the performance differential (Figure 1b,c, dashed axes with origin $(\bar{T}, P_{\bar{T}})$):

$$B(T_b, \bar{T}) = P(T_b) - P(\bar{T}). \quad (1)$$

We assume that benefits arise via locomotion to a more favorable location; however, Equation (1) is general for any form of thermoregulation. The benefit function (Equation 1) implicitly integrates all maintenance costs that are not directly associated with thermoregulation, and, therefore, yields negative values whenever maintenance costs exceed energetic benefits. Huey and Slatkin (1976) suggested that the remaining costs of thermoregulation (those not associated with maintenance; e.g., the energetic costs of locomotion) should be an increasing function of the difference between body temperature and the initial condition ($\Delta T_b = T_b - \bar{T}$) to reflect the growing costs of maintaining body temperatures that deviate further from the modal temperature of the environment. For behavioral thermoregulation, energetic costs can be influenced by the distribution and spatial configuration of environmental temperatures (Huey, 1974; Sears et al., 2016), the morphology, body size, physiology, and search efficiency of the organism, and costs from antagonistic interactions with con- and hetero-specifics (Adolph & Porter, 1993; Grant & Porter, 1992). For these reasons, we define a flexible and symmetric cost function as:

$$C(|T_b - \bar{T}|) = \frac{\beta}{2} (T_b - \bar{T})^2 \quad (2)$$

where β is a positive-valued parameter that determines the second derivative of the cost function with respect to the absolute temperature deviation $|T_b - \bar{T}|$. Large values of β generate a steep function to represent a high cost of thermoregulation, whereas low values generate a flatter function to represent a low cost (Figure 1b blue line = high β ; Figure 1c red line = low β). Our simulations of the energetic costs of movement by organisms using different thermoregulatory behaviors and occurring in thermal environments that differ in the extent, autocorrelation, and distribution of thermal spatial heterogeneity (Figures S1–S7, Appendix 1), reveal that Equation (2) can accurately represent the energetic costs associated with locating favorable microhabitats (Figures S1–S7). We assume a linear relationship between the energetic costs of movement and the other environmental and ecological attributes

that will influence movement (e.g., threats experienced from predators; Waldschmidt, Jones, & Porter, 1986). However, ecological factors associated with specific thermal environments (e.g., high resource densities disproportionately occurring in suboptimal thermal environments) may nonlinearly change the shape of the cost function or may result in unanticipated advantages (Fey & Vasseur, 2016; Rusch & Angilletta, 2017). Thus, the ways in which multiple, sometimes competing factors impact the measured cost functions remains an important avenue for future research.

Given the benefit and cost functions, the body temperature that maximizes individual performance is that which maximizes the difference between $B(T_b, \bar{T}) - C(|T_b - \bar{T}|)$ (T_b in Figure 1b,c), for example, the conditions that maximize the selective advantage defined by $[(B(T_b, \bar{T}) - B(T_b = \bar{T}, \bar{T})) - (C(|T_b - \bar{T}|) - C(|T_b = \bar{T}|))]$. We refer to this as the predicted body temperature in the field. In the limiting case, when the costs of thermoregulation are extremely low, the performance associated with the predicted body temperature in the field approaches the maximum value defined by the thermal performance curve, regardless of mean environmental temperature. Alternatively, when the costs of thermoregulation are exceedingly high, performance converges on that predicted by $P(\bar{T})$. In our framework these two limiting cases (perfect thermoregulation and perfect thermoconformity) form the end points on a continuum of potential behavioral strategies (Huey & Slatkin, 1976).

Changes to the distribution and autocorrelation of \mathbb{T} have different effects on the benefit and cost functions. Alterations to \mathbb{T} generate a translation of the benefit function but do not alter its shape (e.g., shifting \bar{T} to the optimal value for performance shifts the entire benefit function to values ≤ 0); however, the cost function does not display a simple mechanistic response. In all likelihood, the cost parameter β is intricately linked to the thermal landscape. For example, it is likely that β scales inversely with the spatial variance of \mathbb{T} if this increases the frequency of desirable conditions in the landscape (Figure S2). Likewise, spatial autocorrelation can greatly alter travel distances between patches of similar and disparate conditions with greater spatial autocorrelation resulting in higher costs of thermoregulatory behavior (Huey, 1974; Sears & Angilletta, 2015; Figure S1). Without loss of generality, we subsequently examine scenarios where an increase in the mean temperature of the landscape \mathbb{T} is coupled either to a decrease, an increase, or no change in the costs of thermoregulatory behavior.

3 | MATERIALS AND METHODS

3.1 | Mathematical model and analysis of global insect database

We used a cost function with a positive second derivative (see Appendix S1, Figures S1–S7) to explore how different cost scenarios impact estimates of performance. Benefit functions for each of these species that describe performance in relation to temperature

can be derived from thermal performance curves. For the cost function, however, we have no a priori expectation for how differences among species, habitat, geo-location, and life history are manifested. We instead employed a set of nine cost scenarios that arise from crossing three assumptions about the basal cost of thermoregulation $b_0 = \{0.15, 0.5, 2.0\}$, with three assumptions about the temperature dependence of such costs $b_1 = \{-1, 0, 1\}$ using Equation 2 (Figure S8). Based on the ability of some species to maintain stable body temperatures in spatially heterogeneous environments with high mean temperatures (Sears et al., 2016), the lower end of the costs represent a conservative estimate of the conditions that wild organisms face in nature.

Estimates of performance for a hypothetical organism were determined based on a benefit function defined by $w(T_b) = a \times \exp(b \times T_b) - [c + d \times \exp(e \times T_b)]$ (Thomas et al., 2017), and by previously described thermal fitness curves for the insect database compiled by Deutsch et al. (2008). For many representations of $w(T_b)$, the body temperature that maximizes fitness can be analytically solved as a function of T_b ; however, the use of a piecewise

function for thermal performance (e.g., those in Deutsch et al., 2008) requires numerical maximization. The insect analysis of historic (the decade preceding when the thermal performance curve was described) and future (2050–2059) temperature distributions were determined according to the previously described methods (Vasseur et al., 2014) based on low-cost (Figures 2c and 4) or multiple-cost environments (Figure S9). We consider a mean performance at or below 0, equivalent to local extirpation of the population. Computations were performed using Mathematica v. 10.0.

3.2 | Southern rock agama data collection and analysis

The southern rock agama (*Agama atra*) is a highly territorial, insectivorous lizard that lives on rock outcrops throughout a large portion of Southern Africa. Males actively defend small territories that are typically composed of several adjacent boulders. We characterized the thermal heterogeneity of three individual lizard territories

FIGURE 2 The extent to which thermoregulatory behavior modifies population fitness depends on its cost. (a) Three scenarios for whether the cost of behavioral thermoregulation decreases (blue, A1), is invariant (yellow, A2), or increases (green, A3) with an increase in mean temperature, \bar{T} . Predicted body temperatures (b; left panel) and corresponding performance (b; right panel) for a hypothetical organism based on environments with different relationships between \bar{T} and cost scaling scenarios; black lines show a scenario where behavior is not allowed. (c) The performance (mean \pm 1 SE) of a hypothetical ectotherm in a thermal environment with a mean temperature below (left panel, 25°C and standard deviation $\sigma = 2$) and above (right panel, 33°C and standard deviation, $\sigma = 2$) its T_{opt} of 29°C; colors correspond to the cost scenarios in (a); light shading indicates the extent to which behavior can increase performance

at Jonaskop (~34°S, 1,500 m a.s.l.), Western Cape Province, South Africa using 30 physical models in each territory ("operative temperature models" or OTMs; see Appendix S2). Subsequently, we measured the thermal dependence of the running speed of 37 adult male lizards at the same site across a range of body temperatures: 15, 25, 30, 35, 38, 42, and 44°C (see detailed methods in Appendix S2, Figure S10, Table S2).

We determined the relationship between the cost of thermoregulation and the spatial mean temperature, as well as between spatial standard deviation and mean temperature using fixed effects linear models. To estimate the energetic costs for *A. atra* within a territory, we generated one thermal landscape per lizard territory at each 15 min interval by arranging operative temperature measurements into a 5 by 6 array. To predict operative temperatures in the spaces between loggers, we linearly interpolated the thermal configuration of each territory as a 40 by 40 square array to assemble a total of 2,729 individual landscapes for this temporal window. We utilized previously described methods (see model analysis) to numerically estimate the cost function associated with each landscape as the mean distance needed to reach any possible temperature and predicted performance both with and without behavior at each time point.

To predict the performance of *A. atra* in response to climate warming, we increased \bar{T} to +5°C above the measured \bar{T} , and evaluated performance with and without behavior for each temperature regime. As such, this scenario assumes that climate warming will occur uniformly and will not affect the existing relationship between environmental temperature and the cost of thermoregulation. We examined the impact of the cost–mean temperature relationship on performance by fitting a linear model between these variables (Figure 3b). We then adjusted this slope to more negative (e.g., a steeper negative relationship between mean temperature and movement cost) and less negative (e.g., values approaching zero and positive numbers) values, while preserving the predicted cost associated with the grand mean of these data.

3.3 | Geographic variation in the importance of behavior

Using the dataset compiled by Deutsch et al. (2008), we quantified the importance of behavior in historical and future climate regimes for 38 species of insects. We utilize the same methods presented by Vasseur et al. (2014) to determine the average long-term performance for a decade of historic thermal conditions (those most appropriate for the time and location at which the species were collected) and future 2050 scenario (modeled using CGCM3.1/T47), modified to include the behavioral filter described in this paper. We modeled the cost function by setting $\beta = c_0 e^{c_1(T-20)}$, where c_0 sets the basal cost and c_1 determines the cost by temperature scaling. We evaluated the dataset using $c_0 = \{0.15, 0.5, 2.0\}$ and c_1 on the interval $(-0.25, 0.25)$. The output shown in Figure 4a,b assumes a low basal cost ($c_0 = 0.15$) and a moderate negative relationship between cost and temperature ($c_1 = -0.1$). Other values of these parameters give

FIGURE 3 The cost of thermoregulatory behavior influences the predicted performance of southern rock agamas. (a) Spatial standard deviation in environmental temperature increases with mean temperature, \bar{T} , within individual lizard territories; (b) the cost of thermoregulatory behavior (C in Equation 2) decreases as mean temperatures increase. The dashed black line indicates no relationship between \bar{T} and cost. (c) Increasing the existing cost–mean temperature slope (plus sign in panel b) decreases predicted *Agama atra* performance, especially in warmer environments. Dashed lines represent performance estimates without behavior in current (blue) and warmed (red) environments; solid lines represent performance estimates with behavior with different cost–mean temperature slope relationships. The triangle and circle indicate performance estimates with and without behavior given the existing \bar{T} /cost scaling (normalized to -1), respectively. 0 indicates no relationship between cost and mean temperature (dashed line in b), and positive values indicate a positive relationship between cost and mean temperature; \bar{T} are equivalent in all instances

qualitatively similar patterns but alter the extent to which behavior impacts performance (see Figure S9).

4 | RESULTS

4.1 | Evaluating opportunities for behavioral rescue

Our model predicts that behavior exerts the greatest effect on field performance when average movement costs are low (e.g., when available thermal heterogeneity is high and spatial autocorrelation is low; Figures S1 and S2) or when the cost of thermoregulatory behaviors decrease with increasing spatial mean temperature (Figure 2 blue), which is consistent with previous findings (Huey, 1974; Sears et al.,

2011). In these instances, the accelerating rate at which the benefits of thermoregulation accrue (dB^2/dT_b^2) relative to the rate at which costs increase (dC^2/dT_b^2) are conducive to thermoregulatory behavior (Figure 2a) and this behavior ultimately elevates performance (Figure 2b,c). Driven by the shape of the thermal performance curve, the benefits of thermoregulation accrue most rapidly when individuals inhabit an environment with a \bar{T} above which maximal performance is achieved, T_{opt} (Figure 2b, Figure 2c left vs. right panel), also noted by Martin and Huey (2008). Conversely, in environments with temperatures lower than the T_{opt} , our model predicts lesser change in performance from incorporating behavior because benefits of behavior accrue slowly (Figure 2b,c), supporting the general observation that thermoregulatory behavior is used by many ectotherms to decrease body temperature (Grant & Dunham, 1988; Kearney et al., 2009; Logan et al., 2015; Sunday et al., 2016). Yet, we do not negate

the importance of behavioral thermoregulation strategies that increase body temperature above \bar{T} (e.g., basking; Huey et al., 2003). Thus, behavioral thermoregulation becomes critically important as climate warming pushes environmental temperatures above T_{opt} and effective behavioral buffering in these potentially novel conditions requires the availability of thermally suitable microsites.

4.2 | The potential for behavioral rescue in an African lizard

We apply our framework using data collected in the laboratory and field for an African lizard, the southern rock agama (*A. atra*). We collected high-resolution spatiotemporal operative temperature data at the scale of individual lizard territories (Figures S11 and S12) and characterized the thermal performance curves for lizards within this

FIGURE 4 Constraints and opportunities for behavioral rescue vary with latitude. Estimated historic (a) and future (b) performance of 38 insect species assuming no behavior (closed circles) and behavior (open triangles) across latitudes (dash lines depict subtropical latitudes between ~ 23 and 40°). The inset (box plot) describes the mean performance of all species with (solid) and without (dashed boxes) thermoregulatory behavior. (c–e) Performance as a function of the relationship between the cost of thermoregulation and mean temperature, \bar{T} , in temperate (c), subtropical (d), and tropical (e) regions. Dashed lines represent performance estimates without behavior in historic (dashed blue) and 2050 (dashed red) environments; solid lines represent performance estimates allowing behavior in historic (solid blue) and 2050 (solid red) environments. Negative x-axis values indicate a negative relationship between mean temperature and the cost of thermoregulation; vertical lines are the cost-structure values used in panels a and b. See Figure S9 for a detailed list of performance versus cost scaling relationships for all species

population (see Materials and Methods) to investigate (a) the extent to which behavioral buffering can ameliorate the detrimental impacts of warming, and (b) the relationship between increasing mean temperature and the likelihood of behavioral rescue (e.g., Figures 2a and 4c–e). We observed a positive linear relationship between mean temperature and the spatial standard deviation of operative temperatures within territories (Figure 3a). The slope of this relationship remained positive for all active hours (Figure S13), and after restricting the maximum temperature microhabitat the lizards could inhabit (Figure S14). Consistent with our hypothesis, the cost of thermoregulation as measured by c (Equation 2) decreased as \bar{T} increased (Figure 3b, Figure S15).

Forecasts of *A. atra* performance that include movement behavior differ substantially from those that do not include behavior (Figure 3c). Given the observed negative relationship between the cost of thermoregulation and warming in *A. atra* territories, our framework predicts that warming will provide a slight increase in agama performance when movement behavior is allowed (Figure 3c, triangle) relative to estimates of current performance that exclude behavior. By contrast, we anticipate a ~90% decrease in performance when behavior is not allowed (Figure 3c, circle). To determine the importance of the link between warming and thermoregulatory costs, we varied the strength and sign of this relationship in a simulated landscape. In thermal environments with identical \bar{T} , but with different relationships between thermoregulatory cost and mean temperature, the potential for behavioral buffering can be substantially reduced and performance markedly declines with warming (Figure 3c, red solid line). Thus, the behavioral buffering predicted for these lizards occurs because the hottest time periods coincide with the greatest spatial variation in environmental temperature, thereby reducing the cost of thermoregulatory behavior at the point when behavior is most critical in maintaining physiologically optimal body temperatures. *A. atra* are, therefore, predicted to be able to maintain sufficiently low body temperatures during hot periods and their body temperatures rarely exceed their critical thermal maximum.

4.3 | Geographic variation in the importance of behavior under climate change

We applied our framework to population growth rate estimates of 38 insect species from around the globe (Deutsch et al., 2008), assuming the same cost structure applies to all species. We evaluated the potential for behavior to alter vulnerability to climate change by explicitly considering how the net benefits of thermoregulatory behavior change across latitude. By estimating the performance of each population in historic and future climates, while either allowing or not allowing behavior (see Materials and Methods), we determine the conditions that favor a large impact of behavior on performance.

In the absence of thermoregulatory behavior, future insect performance decreased by 14% on average relative to historic performance based on projected local environmental temperatures for 2050 (see Materials and Methods). Irrespective of the assumptions made about the cost of thermoregulation, movement behavior was estimated to have a negligible impact on historical estimates of performance (Figure 4a). By contrast, thermoregulatory behavior has an increased

and potentially critical role in future environments because \bar{T} increasingly rises above T_{opt} for extended periods of time (Figure 4b).

The inclusion of thermoregulatory behavior in models that predict the effects of thermal regimes on performance can lead to predictions of increased performance, but the extent of this improvement is largely contingent upon the costs of behavior and how such costs change with mean temperature (Figure 2c; Figure S8). The true structure of the cost function remains largely unresolved. Such “behavioral buffering” can alleviate much of the detrimental impacts of warming if the cost of thermoregulatory behavior lessens as mean temperature increases. For example, of the 19 insect species we estimate to be negatively impacted by climate warming, our model predicts that behavior will help alleviate this impact for 17 species, including six instances of “behavioral rescue” whereby behavior saves a population that would otherwise be rendered inviable (estimated performance <0) by climate change. Furthermore, for 10 species, the inclusion of behavior causes the effects of warming to vary from negative to positive (Figure 4; Figure S9). Nevertheless, if the cost of thermoregulatory behavior increases with mean temperature, behavioral thermoregulation will have little capacity to buffer climate warming (Figure 2b,c, green).

Our model predicts that behavior will have the greatest capacity to ameliorate the detrimental impacts of warming in subtropical latitudes (± 23.4 – 40° latitude, Figure 4; Table S1), paralleling our findings for the subtropical *A. atra* (Figure 3). Here, effective behavioral buffering is predicted in 65% of subtropical insect species, compared to only 11% and 17% of species in temperate ($>40^\circ$ latitude) and tropical ($<23.4^\circ$ latitude) regions, respectively. Of subtropical species, thermoregulatory behavior has the potential to rescue six species (26% of all subtropical species in the dataset) from local extirpation (Figure 4b). By contrast, behavioral rescue is less likely in temperate and tropical regions where predicted warming produces fewer detrimental impacts (only 22% and 33% of temperate and tropical species are forecasted to have reduced performance relative to historical levels, respectively; Figure 4a–d). The effect of behavior was especially low in temperate regions, where greater thermal performance breadths result in weaker benefits of thermoregulation (Figure 4c). Thus, the impact of spatial heterogeneity in the thermal environment is not equally important for all species and geographic regions.

5 | DISCUSSION

Our framework indicates substantial potential for behavior to mitigate the predicted negative effects of climate warming on animal populations. Yet, predicting which species will benefit the most from thermoregulatory behavior depends on the relationship between the features of the thermal environment, such as the association between thermal variability and mean temperature across ecosystems, and the ability of an organism to utilize the available thermal variability. It seems likely that a positive correlation between the mean environmental temperature and spatial heterogeneity in temperature is common in nature at spatial scales relevant for organisms. Indeed, this

relationship has been demonstrated for other taxa and habitats. For example, spatial heterogeneity in an agricultural system increases with mean environmental temperature (Faye, Rebaudo, Carpio, Herrera, & Dangles, 2017), which reduces the distance required for crop pests to reach a variety of thermal microhabitats (Faye et al., 2017). Similarly, habitats containing thermal refugia—often defined as locations with lower amplitude temperature fluctuations through time (Logan et al., 2013; Scheffers, Edwards, et al., 2014; Scheffers, Evans, et al., 2014)—will become increasingly spatially heterogeneous as \bar{T} increases because the difference between refugia and the rest of the habitat will correspondingly diverge. Likewise, extreme cold events were accompanied by decreased thermal spatial variability for fish in the Everglades National Park, limiting the movement behavior of Common Snook (Boucek, Heithaus, Santos, Stevens, & Rehage, 2017).

However, it is not merely enough to observe an increase in spatial heterogeneity as environments warm to assume that the costs of behavioral thermoregulation will decrease. This requires understanding of not only how the thermal landscape changes, but also how organisms will utilize the altered landscape, particularly in locations representing environmental extremes (Figure S7). Fully resolving the relationship between \bar{T} and thermal characteristics, understanding how climate warming may alter such relationships (Caillon et al., 2014), and anticipating how organisms will utilize the new thermal landscape should be a priority for future research.

Our analysis of insect species assumes that benefit functions are representative of the gains in performance made by all individuals of a given insect taxon and that the cost function is a reasonable fit to all individuals regardless of the location or taxon. Most of the thermal performance curves on which our predictions rely are measured in the laboratory by averaging or aggregating across multiple individuals, yet the cost and benefit functions that we derive are based on the energetic gains and losses of individuals. Much has yet to be learned about the importance of intraspecific variation in thermal performance (Moran, Hartig, & Bell, 2016) and this will surely lead to novel insights on the role of behavior. Furthermore, variation in costs among species, across ecological contexts (Luhring & DeLong, 2016), and across space and time will undoubtedly affect the potential for behavioral rescue and is an avenue worthy of future research.

While intended to represent a first approximation of the costs of thermoregulatory behavior imposed by the environment, the patterns predicted by our framework are consistent with the movement behavior of organisms in nature. Sears et al. (2016) experimentally manipulated spatial heterogeneity in an open desert habitat and demonstrated that lizards maintain tighter control over their body temperatures and incurred smaller energetic costs in habitats with a greater range, and lower spatial autocorrelation, of environmental temperatures. Furthermore, lizard body temperatures mimicked operative temperatures until reaching a high threshold temperature (~33°C), at which point thermoregulatory behavior was used to maintain a near constant body temperature even as the mean environmental temperature continued to increase. Similarly, Logan et al. (2015) recorded a positive relationship between thermal spatial heterogeneity (standard deviation of temperatures) and activity time of a tropical forest-dwelling lizard

species (*Anolis lemurinus*) and that activity time was much more strongly affected by environmental temperatures above T_{opt} rather than below it. These results suggest that increased thermal heterogeneity can encourage movement behavior by lowering thermoregulatory costs, even in habitats typically considered to be thermally homogenous.

Although behavior provides a potent defense against rapid environmental change, it has been historically excluded from large-scale climate-impact estimates (Woods et al., 2015). Our results provide a straightforward and general approach for integrating behavior into such estimates. Our framework reveals that the relationship between the thermal features of the environment defines the likelihood for behavioral rescue in a given region. Organisms living in environments where the cost of thermoregulation increases with mean temperature may be particularly vulnerable to the effects of warming. Thus, a conservation priority should be to identify and preserve features of habitats that function to increase thermal heterogeneity as environmental temperatures continue to rise.

ACKNOWLEDGEMENTS

This manuscript was initiated by conversations at the 2016 Gordon Research Conference on Predator-Prey Interactions: New Frontiers in Understanding Predator-Prey Interactions in a Human-Altered World. We thank R.B. Huey for highly constructive criticisms of earlier drafts. This project was completed with permission granted by CapeNature (permit no. AAA007-00206-0056) and approved by the Stellenbosch University Research Ethics Committee (Animal Care and Use protocol number SU-ACUD14-00061).

CONFLICT OF INTEREST

We have no competing interests.

AUTHORS' CONTRIBUTIONS

All authors contributed to the development of theory; KA, MLL, and SCT collected empirical data; SBF, DAV, and MIO analyzed data; SBF and DAV wrote the initial draft of the paper and all authors contributed substantially to revisions.
